FRED-QD: A Quarterly Database for Macroeconomic Research

Michael W. McCracken* Serena Ng†

March 13, 2020

Abstract

In this paper we present and describe a large quarterly frequency, macroeconomic database. The data provided are closely modeled to that used in Stock and Watson (2012a). As in our previous work on FRED-MD, our goal is simply to provide a publicly available source of macroeconomic "big data" that is updated in real time using the FRED database. We show that factors extracted from this data set exhibit similar behavior to those extracted from the original Stock and Watson data set. The dominant factors are shown to be insensitive to outliers, but outliers do affect the relative influence of the series as indicated by leverage scores. We then investigate the role unit root tests play in the choice of transformation codes with an emphasis on identifying instances in which the unit root-based codes differ from those already used in the literature. Finally, we show that factors extracted from our data set are useful for forecasting a range of macroeconomic series and that the choice of transformation codes can contribute substantially to the accuracy of these forecasts.

JEL Classification: C30, C33, C82

Keywords: big data, factors, forecasting.

1 Introduction

In our previous work, McCracken and Ng (2015), we describe and investigate a monthly frequency database of macroeconomic variables called FRED-MD. At some level, FRED-MD is not particularly innovative. It is, after all, just a collection of $N = 128$ standard U.S. macroeconomic time series, dating back to 1959:01, that have primarily been taken from FRED, maintained by the Federal Reserve Bank of St. Louis, and organized into a .csv file. That description, however, misses the point. Our main goal was to facilitate easy access to a standardized example of a data-rich environment that can be used for academic research. By automating this data set, and maintaining a website that provides monthly frequency vintages, those who are interested in conducting research on big data can focus on the statistical problems associated with big data rather than having to put the data set together themselves. This frees the practitioner from dealing with issues related to, for example, updating the data set when new data is released, managing series that become discontinued, and splicing series from different sources. More prosaically, FRED-MD facilitates comparison of methodologies developed for a common purpose.

FRED-MD has been successful. It has been used as a foil for applying big data methods including random subspace methods (Boot and Nibberin, 2019), sufficient dimension reduction (Barbarino and Bura, 2017), dynamic factor models (Stock and Watson, 2016), large Bayesian VARs (Giannone, Lenza, and Primiceri, 2018), various lasso-type regressions (Smeekes and Wijler, 2018), functional principal components, (Hu and Park, 2017), complete subset regression (Kotchoni, Lerous, and Stevanovich, 2019), and random forests (Medeiros, Vasconcelos, Veiga, and Zilberman, 2019). In addition, these various methods have been used to study a wide variety of economic and financial topics including bond risk premia (Bauer and Hamilton, 2017), the presence of real and financial tail risk (Nicolò and Lucchetta, 2016), liquidity shocks (Ellington, Florackis, and Milas, 2017), recession forecasting (Davig and Hall, 2019), identification of uncertainty shocks (Angelini, Bacchiocchi, Caggiano, and Fanelli, 2019), and identification of monetary policy shocks (Miranda-Agrippino and Ricco, 2017). Finally, and perhaps most rewarding, is that it is described as the inspiration to the development of a Canadian version of FRED-MD (Fortin-Gagnon, Leroux, Stevanovic, and Surprenant, 2018).

While useful, FRED-MD has a glaring weakness. It does not include quarterly frequency data and thus does not provide information on Gross Domestic Product, Consumption, Investment, Government spending, and other macroeconomic series that come from the

National Income and Product Accounts (NIPA). This is unfortunate because there are plenty of examples in the literature in which a quarterly frequency, data-rich environment is used for economic analysis. Examples include Stock and Watson (2012a,b), Schumacher and Breitung (2008), Gefang, Koop, and Poon (2019), Rossi and Sekhposyan (2014), Gonçalves, Perron, and Djogbenou (2017), Carrasco and Rossi (2016), Koopman and Mesters (2017), and Koop (2013).

In this paper we extend our previous work to a quarterly frequency data set we call FRED-QD. The data set is currently operational and provided at the same website in which FRED-MD is maintained. As we did with FRED-MD, FRED-QD is benchmarked to previous work by Stock and Watson (S&W; 2012a). There, the authors organized a collection of $N = 200$ quarterly frequency macroeconomic series dating back to 1959:$Q1$ that they then used to analyze the dynamics of the Great Recession. Our quarterly frequency version of their data set contains nearly all the series they used but, in addition, includes 48 more series with an emphasis on including series related to Non-Household Balance Sheets. In total, the data set consists of $N = 248$ quarterly frequency series dating back to 1959:$Q1$.[1] While many of the series are actually quarterly series, some are higher-frequency series that have been aggregated up to the quarterly frequency - typically as quarterly averages of monthly series.

It's worth noting that we provide the data in levels - without transforming them in any way. As such, some are stationary in levels while others likely need to be transformed by taking logs, differencing, or both to reasonably be considered stationary. For each series we provide benchmark transformation codes. If the series was in the S&W data set we provide their transformation codes. For the additional series, many are taken from FRED-MD and we therefore provide those benchmark transformation codes. One reason to do this is to facilitate replication of the factor analysis provided in S&W as well as other results that may have used a similar data set. Even so, given the well-documented changes in volatility and persistence of macroeconomic series described in Campbell (2007) and Stock and Watson (2007), it may be a good idea to reconsider the default transformation codes.

[1]FRED-QD does not contain ten series that are in the original S&W data set. Using the S&W numbering system these are #88 (Construction contracts), #130 (Index of sensitive materials prices), #131 (Spot market price index of commodities), #165 & #166 (measures of credit spreads & excess bond premia developed in Gilchrist and Zakrajsek, 2012), #95 & #132 (ISM index of supplier deliveries and ISM commodity price index), #152 & #164 (3-month Eurodollar deposit rate and its spread with a 3-month T-bill), and #187 (Dow Jones industrials index). In all but two cases, these are series not available in FRED. Three month Eurodollar deposit rates are in FRED but are not updated on a regular basis because the source (i.e., the OECD) does not update them regularly. The last of these, #187, has been replaced with the S&P 500 industrials index.

After providing more details on the data, we investigate this possibility through the lens of unit root tests. While it is often the case that the unit root tests align with the original transformation codes, the tests are not uniformly supportive.

We then investigate whether factors extracted from FRED-QD are useful for forecasting macroeconomic aggregates. In particular we focus on whether the unit root-implied transformation codes matter for factor-based forecasting.[2] Among the series that we forecast we find that for real and financial series, factors estimated using the unit root-based transformation codes can provide additional predictive content but are more often dominated by those using the original transformation codes. In contrast, we find that when forecasting nominal price series, forecast accuracy is typically better when using factors estimated using the unit root-based codes. This result coincides with evidence provided by Medeiros et al. (2019) and Coulombe et al. (2019), who find that treating price inflation as I(0) leads to better forecasts of inflation than treating it as I(1) - which is precisely what the benchmark transformation codes recommend.

The remainder of the paper proceeds as follows. Section 2 provides a more detailed description of the series in FRED-QD, as well as choices that were made when putting them together. Section 3 presents a brief analysis of the behavior of factors extracted from our data set with an emphasis on their relationship with factors extracted from the original S&W data set. Section 4 constructs statistical leverage scores as a means of identifying which series and data points have the greatest influence on the factors. Section 5 provides a detailed investigation of the degree to which unit root tests agree with the benchmark transformation codes. Section 6 investigates the degree to which factors are useful for forecasting, with particular attention to whether the unit root determined transformation codes improve the accuracy of the forecasts relative to the original codes. Section 7 concludes. A detailed list of the series is provided in the appendix.

2 FRED-QD

As with FRED-MD, the goal of FRED-QD is to provide a readily accessible, easy-to-use macroeconomic database that can form the basis of research in big data. To do so, we make the data set publicly available at the same website as FRED-MD so that anyone can have

[2] Throughout we focus on factors that are $I(0)$. In contrast, Choi and Jeong (2018) provide theoretical and empirical results comparing the forecast accuracy of factors when one has the opportunity to construct them so that they are either $I(0)$ or $I(1)$. In the context of autoregressive models, Diebold and Kilian (2000) provide simulation evidence on a similar issue.

access.[3] Importantly, a new vintage of the data set is created on the last business day of each month. This means that at the end of each month, (i) the most recent data releases have been added, (ii) revisions to the series in previous quarters have been taken on board, and (iii) institutional changes to existing series, periodically made by the statistical agencies, have been appropriately accounted for (e.g., a substitute series is found for a discontinued series).

Based on feedback we received for the FRED-MD project, the most recent vintage is always given a hotlink denoted "current." This allows the user to include that link within their code and thus always have access to the most recent vintage without having to go to the website manually and download the file. Previous vintages of the data set are retained on the website. By retaining the older vintages we facilitate replication of other research that has used FRED-QD. For example, if a researcher develops a new statistical method for working with big data, and wants to compare their results with that from an existing paper, one can go back and find the exact vintage of FRED-QD used in that paper so that differences in results can be attributed to the method rather than the data set.

On the website, we also provide a "Changes to FRED-QD" file that keeps a running tally of modifications that have occurred across the history of FRED-QD. For example, when creating the September 2018 vintage of FRED-QD, three Non-Household Balance Sheet series were discontinued and replaced with comparable series. This event, and the subsequent changes in mnemonics, was documented in the Changes file. It's worth noting that changes can also arise due to issues not associated with statistical agencies. For example, legal issues regarding FRED's ability to post a given series, or to do so only with a substantial delay, sometimes arise. Examples of such are provided in the Changes to FRED-MD file, and one can expect similar issues to ultimately arise in FRED-QD.

With these issues in mind, FRED-QD consists of 248 quarterly series. A full list of the data is given in the Appendix. FRED-QD seeks to keep roughly the same coverage as the S&W data set while allowing the experts at FRED to handle data revisions and definitional changes. The series are classified into 14 groups: NIPA; Industrial Production; Employment and Unemployment; Housing; Inventories, Orders, and Sales; Prices; Earnings and Productivity; Interest Rates; Money and Credit; Household Balance Sheets; Exchange Rates; Other; Stock Markets; and Non-Household Balance Sheets. These groups are similar to, but not the same as, those used in S&W. The original groups included (i) Housing Starts, (ii) Housing Prices, and (iii) Stock Prices, Wealth, & Household Balance Sheets, which we

[3] https://research.stlouisfed.org/econ/mccracken/fred-databases/

have rearranged to form the Housing, Household Balance Sheets, and Stock Markets groups. In addition, Non-Household Balance Sheets is a completely new group.

Of the 248 series, 70 series were not trivially accessed from FRED and needed some kind of massaging prior to being comparable to the corresponding series in S&W. A large portion of those that needed massaging were simply a matter of making nominal series real using a deflator. For each of these series this procedure is explained in the data appendix. For the remaining modified series, a summary of the changes is provided in Table 1. For clarity, all series that required some form of modification are tagged with an "x" to indicate that the variable has been adjusted and thus differs from the series at source.

When producing each vintage of the data set, an additional quarterly observation is added only after the first calendar month of the current quarter, which typically means once the first NIPA data, associated with the previous calendar quarter, is released. For example, the January, February, and March 2019 vintages of FRED-QD report quarterly data associated with 2018:$Q4$ but no data associated with 2019:$Q1$. The first vintage that contains any 2019:$Q1$ data is the April 2019 vintage. Within a calendar quarter, the existing quarterly values can be revised due to monthly frequency revisions of quarterly series like GDP or monthly frequency series like Retail Sales.

Due to data availability and the timing of data releases, FRED-QD is not a balanced panel. As we noted above, we introduce a new calendar quarter to the panel one month into the following quarter. In this vintage, any series that is released with more than a one-month lag is treated as missing (e.g., series associated with the Productivity and Costs release by the BLS). In the following vintage, any series that is released with more than a two-month lag is treated as missing (e.g., series associated with the Financial Accounts of the United States (Z.1) data release by the Federal Reserve Board). In the final vintage for that calendar quarter, all series have typically been released and there are no missing values.[4] As an example, the vintages for July, August, and September 2019 were missing 41, 18, and 0 observations associated with 2019:$Q2$, respectively. Another, less-regular reason for missing observations arises during government shutdowns. For example, U.S. statistical agencies were closed from December 22, 2018 through January 25, 2019. Because this led to delays in the release of many series, the January 2019 vintage of FRED-QD, which typically would be missing 40 or so observations associated with 2018:$Q4$ data, is instead missing 87 observations.

[4] The S&P PE ratio and dividend yield are taken from Shiller's website. These series are updated less consistently than the other series in the dataset. In some idiosyncratic cases, these may be missing for a longer sequence of vintages.

All but thirty-eight series are available starting in 1959:$Q1$. There are a variety of reasons for series to have missing observations at the beginning of the sample: (1) Some series, like Housing Permits, simply didn't exist in 1959:$Q1$ and only became available in 1960:$Q1$. (2) Similarly, the Michigan Survey of Consumer Sentiment is missing two observation at the beginning of the sample because the survey was not conducted on a regular basis until 1959:$Q4$. (3) For other series like the Trade-weighted Exchange Rate, the series is available in FRED only through 1973:$Q1$, and we have not found other documented sources with which to splice the series. (4) Finally, FRED primarily holds NAICS data (though some older SIC data exist and are used whenever possible) from the Census Manufacturers Survey, and hence a few Value of Manufacturer's Orders components like Nondefense Capital Goods and especially Consumer Goods have a limited history.

In many applications of big data, it is expected that the series are stationary. Since it is clear that not all of the series in FRED-QD are stationary in levels, we also provide benchmark transformation codes that are intended to transform the series so that they are stationary. In each instance, a decision is made to treat the series in levels or log-levels, and then, based on whether that series is considered $I(0)$, $I(1)$, or $I(2)$, the variable is differenced to the appropriate degree. For a given series x, these codes take the following forms: (1) no transformation; (2) Δx_t; (3) $\Delta^2 x_t$; (4) $log(x_t)$; (5) $\Delta \log(x_t)$; (6) $\Delta^2 \log(x_t)$; and (7) $\Delta(x_t/x_{t-1} - 1.0)$. For most of the series, these codes are the original transformations used by S&W. For series that we've added, many are monthly series taken from FRED-MD that we have aggregated to a quarterly frequency. For these series we use the benchmark transformation codes reported in FRED-MD. Finally, we also provide an indicator that identifies those series in FRED-QD that were used by S&W to estimate factors.

3 Factor Estimates

In this section we provide an analysis of principal component analysis (PCA)-based factors extracted from FRED-QD. Principal components remain a simple way of transforming the information content in a large number of series into a smaller number of manageable series. Once the components have been extracted they have been used for many purposes, including recession dating (Stock and Watson, 2016), forecasting (Boivin and Ng, 2005), measuring uncertainty (Jurado, Ludvigson, and Ng, 2015), and evaluating monetary policy (Bernanke and Boivin, 2003). Under certain assumptions, principal components provide consistent estimates of common factors and we will use the two terms interchangeably. We are mainly interested in differences in the data through the lens of PCA rather than the method itself.

Another motivation for analyzing the factors is that we have purposefully benchmarked FRED-QD to the large data set of quarterly frequency series used by S&W. In that paper, the authors extract PCA-based factors and use them to disentangle the causes of the Great Recession. Hence, as a means of verifying that we have adequately captured the information in their data set, we also provide a direct comparison of factors extracted from FRED-QD to those extracted from the original data set used by S&W.[5] To do so, we use the September 2019 vintage of FRED-QD, but only those observations and series that were used to estimate factors in the original data set. Keeping in mind that FRED-QD does not have 10 of the series in the original data set, but provides a substitute for one of them, this ultimately gives us $T = 211$ observations ranging from 1959:$Q1$ to 2011:$Q3$ and $N = 125$ or 132 series when using FRED-QD or the original data set, respectively.

Because FRED-QD has missing values and outliers that we treat as missing,[6] we estimate the factors by PCA adapted to allow for missing values. Our approach to doing so is closely related to the EM algorithm given in Stock and Watson (2002). Each series is demeaned and normalized to unit variance using the sample means and standard deviations respectively. If the time $t = 1, ..., T$ observation for series $i = 1, ..., N$ is missing, we initialize it to the unconditional sample mean based on the non-missing values (which is zero since the data are demeaned and standardized) so that the panel is re-balanced. Based on this panel, and for a given number of factors r, a $T \times r$ matrix of factors $F = (f_1, \ldots, f_T)'$ and a $N \times r$ matrix of loadings $\lambda = (\lambda_1, \ldots, \lambda_N)'$ are estimated using the normalization that $\lambda'\lambda/N = I_r$. We then update the missing values for each series from zero to $\hat{\lambda}_i'\hat{f}_t$. This is multiplied by the standard deviation of the series and the mean is re-added. The resulting value is treated as an observation for series i at time t, and the mean and variance of the complete sample are re-calculated. The process of demeaning, standardizing, and estimating the factors and loadings is repeated using the updated panel. The iteration stops when the factor estimates do not change.[7]

We then select the number of significant factors r. We use the IC_p criteria developed in Bai and Ng (2002), which are generalizations of Mallow's C_p criteria for large dimensional panels. The number of factors is chosen to minimize the sum of squared residuals while keeping the model parsimonious. For this analysis, we use the penalty $\frac{N+T}{NT}\log(\min(N, T))$, which is shown by Bai and Ng (2002) to have good finite sample properties. This criterion

[5]The data are currently posted on Mark Watson's website. https://www.princeton.edu/~mwatson/publi.html

[6]See Section 4 for further discussion.

[7]The dominant factors are almost identical when the missing values are imputed using the method in Bai and Ng (2019b).

is referred to as IC_{p2}. For both the original data set and the subset of FRED-QD used for this comparison, IC_{p2} selects $r = 4$ factors.

In Figure 1 we plot the four factors based on each data set. The NBER recession dates are shaded in grey. Visually, each of the four factors is very similar across the entire sample.[8] This is particularly true for the first factor for which the two estimates are nearly identical and have a correlation exceeding 0.99. The remaining three correlations are only marginally lower, with values of 0.988, 0.968, and 0.980 for the second through fourth factors, respectively.

While the figure gives a visual characterization of the similarities of the factors, it is instructive to provide a more quantitative comparison. We do this by identifying which series are best explained by the factors. To do so, we regress the i-th series in the data set on a set of the r factors. For $k = 1, \ldots, r$, this yields coefficients of determination $R_i(k)^2$ for each series i. Because the factors are orthogonal and organized in decreasing order of their respective eigenvalues, the incremental explanatory power of factor k for series i is $mR_i^2(k) = R_i^2(k) - R_i^2(k-1)$, $k = 2, \ldots, r$ with $mR_i^2(1) = R_i^2(1)$. The average importance of factor-k is $mR^2(k) = \frac{1}{N}\sum_{i=1}^{N} mR_i^2(k)$. Table 2 lists $mR^2(k)$ and the ten series with the highest $mR_i^2(k)$ for factor k. The upper panel does so for the factors estimated using FRED-QD, while the lower panel does the same but with the original S&W data set. To simplify interpretation of the factors, we also include the group numbers for each of the ten series.

A quick look at Table 2 immediately reinforces the visual similarity from Figure 1. Regardless of which data set is used to estimate the factors, the total variation explained by all four factors is nearly the same (i.e., 0.41), and the $mR^2(k)$ values are nearly the same as well (i.e., 0.21, 0.09, 0.06, and 0.05 for factors $k = 1, ..., 4$). The similarity also carries over to the top ten series with the highest $mR_i^2(k)$ values. While the rank ordering of the series varies a bit, 10, 8, 9, and 9 of the top ten series coincide across the four factors, respectively. This is convenient because it implies that the interpretation of the factors remains unchanged when using FRED-QD rather than the original S&W data set. The first factor is a real activity indicator that weighs heavily on series from the employment, industrial production, and NIPA groups. The second factor is dominated by forward-looking series such as term interest rate spreads and inventories. The third factor has explanatory power concentrated in the prices group as well as housing sector prices. Finally, the fourth factor is extensively weighted on both the price group and exchange rates.

[8]The factors have been multiplied by -1 where necessary to make the two estimates positively correlated.

Figure 1 and Table 2 suggest that FRED-QD provides a reasonable replication of the original data set - at least through the lens of PCA-based factor analysis. Even so, it also contains additional series not in the original S&W data set, and thus it is reasonable to wonder if those series provide additional information. Using all of the series and observations in FRED-QD, IC_{p2} selects three additional factors bringing the total up to $r = 7$. These are plotted in Figure 2. The first two factors remain closely related to those constructed using the S&W data set with correlations of 0.99 and 0.96, respectively. Beyond that, the correlations drop off dramatically with the third and fourth factors only exhibiting correlations of roughly 0.70.

The similarities and differences are more readily seen in Table 3. There we report the marginal R^2 values associated with the seven factors identified using the entirety of FRED-QD. As expected, the first two factors retain the same interpretation as those reported in Figure 1 and Table 2. The first is a real activity factor that correlates strongly with series in the Employment and Industrial Production groups, while the second remains a forward-looking factor that correlates heavily on interest rate term spreads as well as housing permits and starts. In contrast, while the third factor from the S&W data set was a mixture of consumer prices and housing prices, when estimated using FRED-QD, the third factor is a pure consumer price index with all of the top ten $mR_i^2(3)$ values associated with the Prices group. In contrast, when using the full FRED-QD data set, the fourth factor appears to be a second employment-oriented factor rather than a second prices-oriented factor, as we observed using the S&W data set.

The interpretation of factors four to seven are less clear. While most of these factors exhibit considerable correlation with series in the Earnings and Productivity group (i.e., group 7), a variety of other groups are represented. The fifth factor also correlates with Employment and both the Household and Non-Household Balance Sheet groups, while the sixth factor correlates with several series in the Money and Credit group. Finally, the seventh factor appears to be a weaker version of the fifth factor insofar as it too correlates heavily with several series in the Household Balance Sheet group. It is useful to note that these smaller factors are discarded using the criterion in Bai and Ng (2019a) that guards against outliers, an issue to which we now turn.

4 Outliers and High Leverage Observations

As previously noted, we estimate the factors after first identifying any outliers. In this section we provide a brief investigation into the importance of these outliers and the related concept of high leverage observations. As in S&W, we define an outlier as an observation that deviates from the sample median by more than ten interquartile ranges. By this definition, the S&W data set and the corresponding subset of FRED-QD each have seven outliers. These are identified in 1971:$Q1$ and 1997:$Q1$ for a consumer credit series, in 2008:$Q4$ for three producer price series, and in 2010:$Q2$ for federal employment and consumer loans.[9] The full FRED-QD data has 30 outliers, 17 of which are found between 2008:$Q1$ and 2010:$Q4$ and are predominantly bank reserves variables. Two interest rate variables and a prices variable are also identified to be outliers in 1980:$Q3$/$Q4$, as well as oil price in 1974:$Q1$ and six Non-Household Balance Sheets variables between 2017:$Q4$-2018:$Q1$. As exogeneity of these events is questionable, it is also debatable whether they should be removed. In fact, without the outlier adjustment, the IC_{p2} criterion identifies eight factors in the data instead of seven. Nonetheless, the first six factors estimated with and without outlier adjustments are almost perfectly correlated, suggesting that the effect of outliers on the largest factors is quite minimal.

The statistics literature makes a distinction between outliers and high leverage points.[10] In a regression context, a data point is said to have high leverage if its x values are far from the mean of its x_i values. FRED-QD has 248 series and 242 quarters, and it seems likely that some series and some data points are more important than others. As discussed in Mahoney (2011), statistical leverage scores can be informative about the non-uniform structure of importance in the data. Consider a $T \times N$ data matrix X with singular value decomposition $X = U\Sigma V'$ and assumed to have a low rank component of rank r. The factor estimates reported above can be expressed as $(\tilde{F}, \tilde{\Lambda}') = (\sqrt{T}U_r, \sqrt{N}V_r D_r)$. A different aspect of the eigenvectors will now be explored. Let $u_{(t)}$ be the t-th row of the $T \times r$ matrix of left singular vectors U_r, and $v^{(i)}$ be the i-th column of the $r \times N$ matrix of right singular vectors V_r'. Define the normalized row and column leverage scores as

$$p_t = \frac{\|u_{(t)}\|_2^2}{\sum_{t=1}^T \|u_{(t)}\|_2^2}, \qquad p^i = \frac{\|v^{(i)}\|_2^2}{\sum_{i=1}^n \|v^{(i)}\|_2^2}.$$

As $\sum_{t=1}^T p_t = \sum_{i=1}^N p^i = 1$, these probabilities also define an "importance sampling distribution" for the rows and the columns of X, respectively. The row scores are simply the diagonal entries of the "hat" matrix sometimes used to detect influential observations

[9]For the S&W data, these are REVOLSL, WPU0561, PPIDC, PPITM, CES9091000001, and CONSUMER. For the subset of FRED-QD data, PPITM is replaced by WPSID61.

[10]In a regression setting with predictors x, an observation is an outlier if the residual or its standardized variant is far from its mean. An influential point is one whose inclusion changes the estimates. See Chatterjee and Hadi (1986) and Rousseeuw and Zomeren (1990).

in regression settings. Here, it is used to evaluate the strength of each row of the top r left singular vectors, giving information about the relative importance of the time series data points. The column score evaluates the strength of each column of the top r right singular vectors and hence is informative about the relative importance of the data in the cross-section.

We compute the row leverage scores for the full and balanced FRED-QD data with and without outlier adjustment. The results are similar, and hence to conserve space, in Figure 3 we plot the leverage scores for the full-sample of FRED-QD without outlier adjustment. If the information is uniformly dispersed over time, each of the T observations should have a score of $\frac{1}{T}$. In the FRED-QD data, six data points account for 20% of the mass in p_t: 2008:$Q4$, 2009:$Q1$, 1975:$Q1$, 1980:$Q4$, 1980:$Q2$, and 2009:$Q2$. These roughly coincide with the outliers detected by the method of interquartile range.

Turning to the column leverage scores, each p^i should be $\frac{1}{N}$ if information in the series is evenly dispersed. This is apparently not the case, as the (unreported) histogram of p^i is quite skewed. For the sub-panel of FRED-QD data corresponding to the S&W data set, the series with the top three scores are the US/Euro exchange rate (EXUSEU), WPSID61, and PPIDC regardless of whether an outlier adjustment is made. For the full FRED-QD panel, the series with the top scores are COMPRMS, EXUSEU, GS5 without outlier adjustment, and NWPIx, S&P 500, and real household networth (TNWBSHNOx) with outlier adjustment. Apparently, the variables added to the full panel do change the information content of the panel. Nonetheless, these variables are already known to play an important role in business cycle modeling. This analysis simply reinforces their importance.

5 Transformation Codes

As we noted earlier, the data set provides benchmark transformation codes that are designed to make each series stationary. After having made the decision that the series should be managed in levels or log-levels, the transformation codes are first and second differences based on whether the series is believed to be $I(0)$, $I(1)$, or $I(2)$. In this section we revisit the benchmark transformation codes and do so through the lens of unit root tests. In particular, we apply unit root tests to each series in FRED-QD to see whether or not the unit root tests imply the benchmark transformation codes.

For each series we apply two variants of the Dickey-Fuller GLS tests as delineated in Elliott, Rothenberg, and Stock (1996). These two tests differ only in how the number of autoregressive lags are chosen. One uses the Schwarz's Information Criterion (SIC) to choose the appropriate number of lags, and the other uses a Modified Akaike Information Criteron (MAIC), developed in Ng and Perron (2001).[11] In each case the maximum number of lags is based on the recommendation in Schwert (1989) and hence for a given sample size T, $k_{\max} = \lfloor 12(T/100)^{1/4} \rfloor$.

We use the results of these tests to identify the appropriate transformation codes. For example, recall that for the DFGLS tests, the null hypothesis is that the series is $I(1)$. Hence, if we fail to reject, the series is differenced and the test is repeated until we reject the null. Depending on when this algorithm rejects the null determines the transformation code. For each test, and at each stage of the algorithm, we consider nominally 5% tests of the respective null.

For brevity we do not report the results of all the unit root tests. Instead, in Figure 4 we provide histograms of the implied transformation codes for all the series.[12] In the top diagonal of the first panel is the histogram of the codes reported in FRED-QD. All series have transformation codes of either 1, 2, 5, or 6, and hence no series are considered stationary in log-levels (4) or second differences of levels (3). By far the bulk of the codes are 5s, and hence the series are considered stationary in log-first differences. These patterns change when we consider the unit root-based transformation codes. The largest changes occur when using the MAIC variant of the DFGLS test. Here we find that much of the mass associated with a code of 5 has shifted into a code of 6 leading to more than a doubling of the number of series that require double differencing in log-levels. That said, some mass from the 5s has settled into the 4s, suggesting that some of the series may be $I(0)$ in log-levels rather than log first differences. There is also a modest shift in mass from the 1s and 2s into 3s and hence the tests indicated some of the series are stationary in the second difference of the levels. In contrast, the SIC-based DFGLS test implies more modest deviations from the original transformation codes. There remains almost no mass on the 3s and 4s. The largest deviation from the benchmark codes comes from a shift of mass from the 6s into the 5s and hence the SIC-based test indicates that some of the series have been overdifferenced.

The histograms convey the fact that the unit root tests can imply transformation codes that don't align with the benchmark codes. Nevertheless, they do not convey where the changes are coming from. To address this issue, in Table 4 we report the median transfor-

[11]In unreported results we chose lag lengths based on the the Sequential t-test (Seq.t), as described in Ng and Perron (1995). The results were very similar to those for the MAIC and hence we do not report them for brevity.

[12]We omit nonborrowed reserves from these figures because it is the only series with a transformation code of 7. This code exists because nonborrowed reserves, which should be positive, turned negative during the financial crisis. This precludes the use of transformation code 5.

mation by group. For the MAIC-based tests, much of the shift toward log second differences occurs in the NIPA, Industrial Production, and Earnings and Productivity groups. In contrast, for the SIC-based tests, the biggest change occurs for Prices in which case the test recommends treating Prices as log first differences instead of log-second differences. Both versions of the DFGLS tests disagree with the benchmark codes for Housing, of which several of the series are considered stationary in log-levels and hence do not need to be differenced.

It's clear that the unit root tests recommend changes in some of the transformations. Even so, it's worth keeping in mind that many of the unit root-implied codes continue to coincide with the benchmark codes. It therefore need not be the case that factors based on the benchmark codes deviate significantly from factors based on the unit root codes. In Figure 5 we plot the first four factors based on the benchmark codes along with the corresponding factors constructed after using the unit root test determined codes. For the 1^{st} factor, the SIC- and benchmark-implied factors largely coincide and exhibit a correlation of 0.95. In contrast, the MAIC-based variant deviates substantially from that constructed using the benchmark codes, with which they have a modest correlation of 0.56. For the remaining factors, substantial differences exist among the unit root-implied factors and those based on the benchmark codes.

In Table 5, more detailed evidence on the differences in the factors can be gleaned from the marginal R^2 values for the factors plotted in Figure 5. Rather than go through these in detail we make only a few notable observations. One noticeable distinction among the factors is that while the MAIC-based factors remain heavily concentrated in the employment and industrial production groups, the $mR^2(1)$ values are substantially lower than those associated with the benchmark and SIC-based codes. This likely follows from the propensity of the MAIC-based unit root tests to treat many NIPA and employment series as $I(2)$ rather than $I(1)$, which, apparently, leads to a loss of information due to overdifferencing. Another is the relatively clear interpretability of the SIC-based factors. The first factor is a clear employment factor, while the second is a pure consumer prices factor. The third is arguably an unemployment factor, and the fourth is heavily correlated with producer prices with an emphasis on energy and, specifically, oil prices.

6 Predictability of Factor-based Models

In this section we investigate the usefulness of factors for predicting macroeconomic aggregates. The structure of the forecasting exercise is motivated by a similar forecasting exercise conducted by Stock and Watson (2012b). Specifically, we construct 1- and 4-quarter-ahead forecasts of Real GDP (log-level), Industrial Production (log-level), the Unemployment rate (level), and the Federal Funds Rate (level), as well as the CPI, PCE, GDP deflator, and PPI price indices (each in log-level). These variables were chosen based on the results of the unit root tests in the previous section, with an eye toward emphasizing the role that transformation codes have on the predictive content of factors. For each permutation of the eight dependent variables Y and two horizons h, we have three goals: (1) document that the FRED-QD factors have predictive content above-and-beyond that contained in a baseline autoregressive model, (2) document whether the choice of transformation codes can have a material effect on the predictive content of factors extracted from FRED-QD, and (3) document those factors that exhibit the most predictive content for the target variables.

In each case, the models used for forecasting take the direct multistep form

$$y_t^{(h)} = \alpha_h + \sum_{j=0}^{p-1} \beta_j^{(h)} y_{t-h-j} + \delta^{(h)\prime} f_{t-h} + \varepsilon_t^{(h)} \tag{1}$$

where

$$y_t^{(h)} = \left\{ \begin{array}{cc} Y_t & \text{if } Y_t \text{ is } I(0) \\ Y_t - Y_{t-h} & \text{if } Y_t \text{ is } I(1) \\ Y_t - Y_{t-h} - h\Delta Y_{t-h} & \text{if } Y_t \text{ is } I(2) \end{array} \right\}. \tag{2}$$

For brevity, when $h = 1$ we drop the superscript and define $y_t^{(1)}$ as y_t. At each forecast origin the model is estimated by OLS, and the h-step-ahead forecast of $y_{t+h}^{(h)}$ is then constructed as

$$\hat{y}_{t,h}^{(h)} = \hat{\alpha}_{h,t} + \sum_{j=0}^{p-1} \hat{\beta}_{j,t}^{(h)} y_{t-j} + \hat{\delta}_t^{(h)\prime} f_t. \tag{3}$$

Forecasts of Y_{t+h} are then computed in accordance with the order of integration of Y:

$$\hat{Y}_{t,h} = \left\{ \begin{array}{cc} \hat{y}_{t,h}^{(h)} & \text{if } Y_t \text{ is } I(0) \\ Y_t + \hat{y}_{t,h}^{(h)} & \text{if } Y_t \text{ is } I(1) \\ Y_t + h\Delta Y_t + \hat{y}_{t,h}^{(h)} & \text{if } Y_t \text{ is } I(2) \end{array} \right\}. \tag{4}$$

Following Stock and Watson (2012b), we fix the number of autoregressive lags p at 4 and only consider a single lag of the factor(s). Since it is not obvious which of the 7 factors should be used to forecast any particular target variable, and since those factors could vary by horizon, we consider all $2^7 - 1 = 127$ possible choices of f_t as a potential predictor. Hence, in some cases, f is a scalar consisting of just one of the 7 possible factors, while in other models f is a vector consisting of up to all 7 factors.

All models are estimated using a rolling window of 106 (109) observations when $h = 1$ (4). The first forecast origin is $R = 1985{:}Q1 + h$, and the last forecast origin is $T = 2018{:}Q4 - h$, for a total of $P = 134$ (128) forecasts. At each forecast origin we estimate the factors two different ways. For the first, we use the benchmark transformation codes provided in FRED-QD. For the second, at each forecast origin we perform unit root tests on all series in FRED-QD using the past 106 (109) observations when $h = 1$ ($h = 4$). Based on the outcome of these tests, we select transformation codes using the same algorithms described in the previous subsection. For brevity, we only consider the SIC-based DFGLS unit root test in this forecasting exercise. Using the MAIC-based unit root test leads to different results. Our goal is not to provide the "correct" set of results, but rather to demonstrate that sticking to previously established transformation codes may lead to inferior results.[13]

It's important to keep in mind that by taking a rolling window approach to forecasting, we have potentially time-varying transformation codes and this has multiple effects on our forecasting exercise. Obviously, different transformation codes lead to distinct estimated factors as shown in Figure 5. In addition, given our direct multi-step forecasting environment, different transformation codes also lead to time varying definitions of $y^{(h)}$. For this reason we measure accuracy of the forecasts relative to Y rather than $y^{(h)}$. In particular, we evaluate accuracy of the forecasts under quadratic loss using mean squared errors $P^{-1}\sum_{t=R}^{T}(Y_{t+h} - \hat{Y}_{t,h})^2$.

For each target variable Y and horizon h, there is a benchmark $AR(4)$ model that is estimated using the original (OLD) transformation codes. In addition, there are 127 models that augment the benchmark $AR(4)$, with at least one factor formed using the OLD transformation codes. The same is done using transformation codes based on the unit-root testing algorithm (NEW). This leads to 128 more models, including an $AR(4)$ based on the NEW codes and 127 models that augment this $AR(4)$ with at least one of the seven factors.

For each of the 254 models that include at least one factor, we conduct a one-sided test of the null that the factors do not contribute finite-sample predictive content relative to the benchmark $AR(4)$. The null is stated in the context of the test of unconditional finite-sample predictive ability advocated by Giacomini and White (2006). However, in contrast to their recommended testing procedure, we follow Coroneo and Fabrizio (2018) and apply a Fixed-b asymptotic approximation to the test statistic. Specifically, for each

[13] In part we focus on the SIC-based factors because of our intution on what some transformations "should" be. For example, MAIC-based tests recommend treating real GDP as $I(2)$ in log-levels. This does not strike us as reasonable.

model $j = 1, ..., 254$ that includes at least one factor, the test statistic takes the form $P^{-1/2}\sum_{t=R}^{T}(\hat{u}^2_{t+h,AR} - \hat{u}^2_{t+h,j})/\hat{\omega}_j$ where $\hat{\omega}^2_j$ is an estimate of the long-run variance of $\hat{u}^2_{t+h,AR} - \hat{u}^2_{t+h,j}$. This is estimated using the Bartlett kernel and bandwidth $\lfloor 1.3\sqrt{P} \rfloor + 1$ as advocated in Lazarus, Lewis, Stock, and Watson (2018). Critical values for the asymptotic distribution are approximated using the formula provided in Table 1 of Kiefer and Vogelsang (2005; p. 1146).

While this testing procedure allows us to ascertain whether the factors exhibit finite-sample predictive content beyond that in the benchmark $AR(4)$, there is an obvious multiple-testing problem. To mitigate the potential for multiple testing, we provide complementary evidence on accuracy using the model confidence set procedure advocated by Hansen, Lunde, and Nason (2011). This allows us to identify the subset of all 256 models that are statistically as accurate as the single most accurate model. Note that this information is related to, but not the same as, the previous test comparing each model to the benchmark. For example, it could be the case that the benchmark is the best model, and hence factors do not provide additional predictive content. Even so, many of the factor-based models may be contained in the model confidence set because they are approximately as accurate as the benchmark. With this difference of interpretation in mind, we use the $T_{R,\mathcal{M}} \equiv \max_{i,j\in\mathcal{M}} |t_{i,j}|$ statistic when implementing the model confidence set procedure. The distribution of this test statistic is approximated using a circular block bootstrap with block length $l = 12$ using software distributed by Sheppard (2018).To help identify the most accurate models, we use a restrictive significance level of 25% - that is associated with the model confidence set $\mathcal{M}_{75}$.[14]

Rather than report all of the testing results, we focus on a concise subset that provides evidence on our three forecasting goals. For each permutation of target variable Y and horizon h, we report the root mean squared error (RMSE) for the benchmark $AR(4)$, along with the relative RMSEs associated with the ten most accurate models. An asterisk denotes whether or not the models were more accurate than the $AR(4)$ at the 5% level using the Fixed-b critical values. In addition, we report the number of OLD and NEW models that outperform the benchmark $AR(4)$. Finally, we report the number of models contained in the model confidence set. Since we want to identify the importance of the transformation codes, we also specify the number of models in the model confidence set that use the NEW factors based on the unit-root driven transformation codes.

[14]In unreported work, we also considered a weaker 10% level of significance. For several of the variables, nearly all of the models were included in the model confidence set despite, what appeared to be, substantial differences in MSEs.

Tables 6 and 7 provide the results. In the first table we focus on the real and financial target variables, while in the second we focus on the price series. In Table 6 we find numerous evidence that the factors can provide additional predictive content beyond that of the benchmark $AR(4)$. For all four target variables and at both forecast horizons, the number of factor-based models that significantly outperform the benchmark range from as low as 3 models when forecasting the federal funds rate at the one-quarter horizon, to as high 142 models when forecasting the unemployment rate at the four-quarter horizon. To be fair, many of those that outperform the benchmark only do so to a modest degree. The largest gains occur for the unemployment rate at the four-quarter horizon where accuracy is improved by a substantial 25%. For the other target variables and/or horizons, the largest gains range from 17% to as low as 3%.

One obvious feature of Table 6 is the dominance of the factors constructed using the OLD transformation codes. Across all target variables and horizons, exactly 16 out of a possible 80 top ten most accurate models are based on factors estimated using the NEW transformation codes. Seven of these instances occur when forecasting GDP growth, another seven occur when forecasting the federal funds rate, and the remaining two occur when forecasting the unemployment rate, and in all cases these occur at the four-quarter horizon. In addition, for all but one permutation of target variable and horizon, there are more models based on the OLD transformation codes that outperform the AR(4) benchmark.

Among those factor-based models that perform in the top ten, it isn't obvious that one particular factor is dominant and should always be used when forecasting. Even so, it is true that at least one of the first two factors (i.e., 1 or 2) occur in all but two top ten factor-based models. While that might suggest that those factors associated with the largest eigenvalues provide the most predictive content, one should not conclude the contributions are monotone. There are many instances, like that when forecasting industrial production at either horizon, where the 2^{nd}, 6^{th}, and 7^{th} factors are included, but the 1^{st}, 3^{rd}, 4^{th}, and 5^{th} are not. It's also worth noting that the number of factors necessary to improve accuracy relative to the benchmark AR(4) varies across series and, to a lesser extent, horizon. When forecasting the federal funds rate, maximal gains are achieved when including only two factors, but when forecasting the unemployment rate, the best models include five factors. In fact, there are instances in which including all seven factors in the model lead to forecasts of the unemployment rate and GDP growth that outperform those based on the benchmark AR(4) model.

Moving to Table 7, that associated with predicting the four price series, we again find substantial evidence that the factors can provide marginal predictive content beyond the benchmark $AR(4)$. In some cases, like when forecasting the GDP-deflator at the four-quarter horizon, the number of factor-based models that have marginal predictive content is as low as 42, but in other cases, like when forecasting PPI at the same horizon, the number is as high as 191. Relative to the benefits of using factor-based models observed in Table 6, the top gains are typically smaller. When forecasting PPI at the four-quarter horizon, the gains are as large as 23% but are less than 10% for all other permutations of target variable and horizon.

But in contrast to the results in Table 6, when forecasting prices, factor-based models using the NEW transformation codes generally dominate those that use the OLD codes. Among the 80 possible top ten models, only 19 are based on models that use the OLD transformation codes. Interestingly, none of these instances occur when forecasting PPI, which is dominated by factors estimated using the NEW transformation codes. In addition, relative to Table 6 there tends to be more models in the confidence set that use the NEW transformation codes. Similarly, relative to Table 6 a larger number of factor models that use the NEW transformation codes outperform the benchmark AR(4) – and do so especially at the longer forecast horizon.

In terms of which factors are most useful for forecasting, there is a bit more heterogeneity when forecasting prices. In Table 6, nearly every top ten model had at least one of the first two factors based on either the OLD or NEW transformation codes. While it is the case that a majority of the top ten models in Table 7 contain one of the first two factors, some of the best models include neither of the first two factors and, instead, include the 4^{th} or 5^{th} factor − this is particularly true when forecasting PPI for either forecasting horizon. Nevertheless, it remains true that many of the top 10 models contain more than just one or two factors and, in fact, several include as many as five or six factors.

7 Conclusion

As was the case for FRED-MD, the purpose of introducing FRED-QD is to provide easy access to a large set of macroeconomic data that can be used to conduct research using "big-data" methods. The primary difference between the two data sets is simply that FRED-QD provides quarterly frequency data and, as such, permits the inclusion of lower frequency series like those from the NIPA releases. Regardless of this difference, like FRED-MD, the data set has been, and will continue to be, updated by the data specialists at FRED on a regular basis to account for newly released data, data revisions, and other complicating

issues that sporadically arise with data collection. We (again!) sincerely thank them for their support in this work.

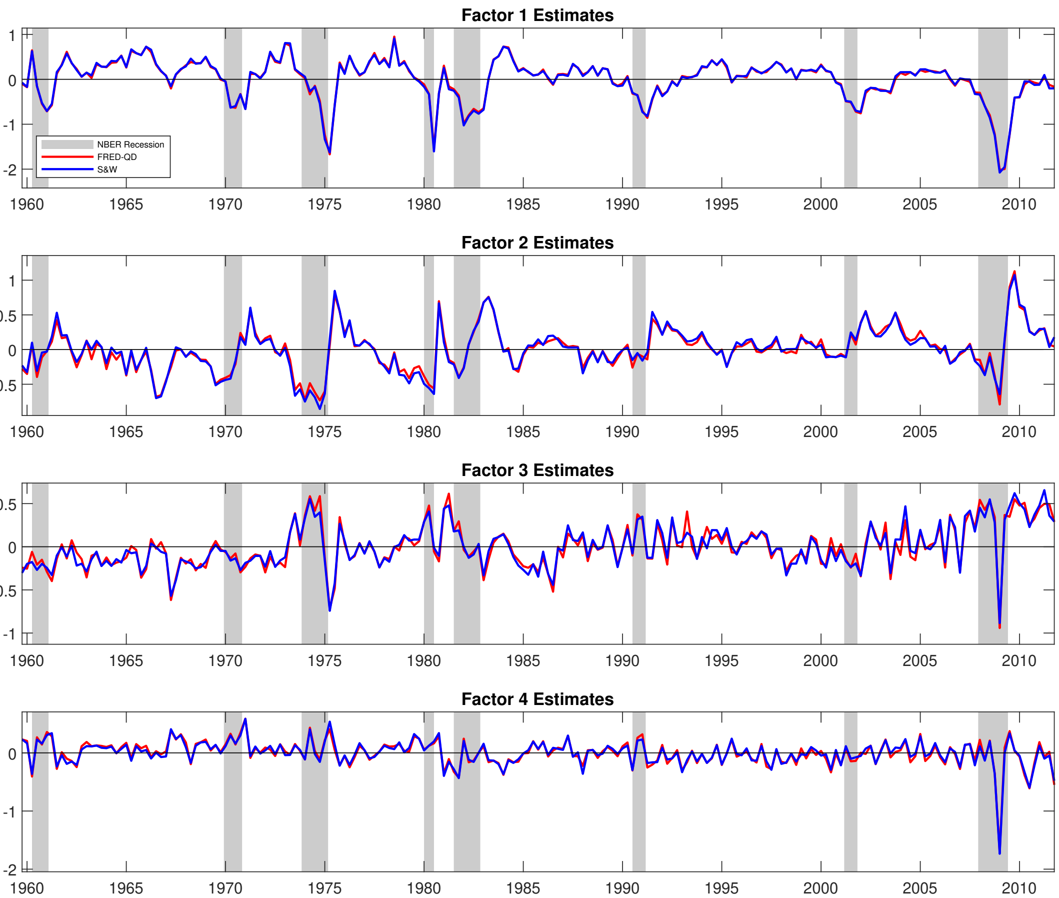
Figures and Tables

Table 1: Series adjusted by FRED-QD

Number	Variable	Adjustment
60	Unemployment Rate (< 27 weeks)	(UNEMPLOY - UEMP27OV)/CLF16OV
61	Unemployment Rate (> 27 weeks)	UEMP27OV/CLF16OV
80	Help-Wanted Index	splice LMJVTTUVUSM647S with Barnichon series
88	Real Manu. and Trade	(i) adjust M0602BUSM144NNBR for inflation using PCEPI
		(ii) seasonal adjust with ARIMA X12
		(iii) splice with NAICS series CMRMTSPL
89	Retail/Food Sales	splice SIC series RETAIL with NAICS series RSAFS
90	New orders (durables)	splice SIC series AMDMNO and NAICS series DGORDER
92	Unfilled orders (durables)	splice SIC series AMDMUO and NAICS series AMDMUO
93	New orders (nondefense)	splice SIC series ANDENO and NAICS series ANDENO
130	Crude Oil	splice OILPRICE with MCOILWTICO
153	30yr Mortage to 10yr Treasury	MRTG - GS10
154	6mth Tbill - 3mth Tbill	TB6M - TB3M
155	1yr Treasury - 3mth Tbill	GS1 - TB3M
156	10yr Treasury - 3mth Tbill	GS10 - TB3M
157	3mth Commercial - 3mth Tbill	CPF3M - TB3M
172	Household/Nonprof Liab to Income	TLBSHNO/PI
174	Household/Nonprof Networth to Income	TNWBSHNO/PI
178	S&P 100 Volatility: VXO	splice Bloom series with VXOCLS
184	Switzerland/U.S. FX	filled back to 1959 from Banking/Monetary statistics
185	Japan/U.S. FX	filled back to 1959 from Banking/Monetary statistics
186	U.K./U.S. FX	filled back to 1959 from Banking/Monetary statistics
187	Cdn/U.S. FX	filled back to 1959 from Banking/Monetary statistics
188	Consumer Sentiment	splice UMSCENT1 with UMSCENT
220	Help Wanted to unemployed	HWI/UNEMPLOY
221	Initial Claims	splice monthly series M08297USM548NNBR with weekly ICSA
222	Business Inventories	splice SIC series and NAICS series BUSINV
223	Inventory to sales	splice SIC series and NAICS series ISRATIO
224	Consumer credit to P.I.	NONREVSL/PI
235	Business Liabilities to Income	TLBSNNCB/BDI
238	Business Net Worth to Income	TNWMVBSNNCB/BDI
240	NonCorp Busi. Liabilites to Income	TLBSNNB/BDI
243	NonCorp Busi. Net Worth to Income	TNWBSNNB/BDI
244	Business Income	(CNCF - FCTAX)/IPDPS

Figure 1: FRED-QD and S&W Factor Estimates



Note: This figure shows the estimates of factors 1-4 for both the S&W and FRED-QD data sets. For estimation of factors in the FRED-QD data set, only series and observations that correspond to those in the S&W data set are used.

Table 2: Factor Estimates from FRED-QD and S&W: Total Variation Explained, 0.413

FRED-QD

Total variation explained by factors: 0.413											
$mR2(1)$	0.211	G#	$mR2(2)$	0.091	G#	$mR2(3)$	0.063	G#	$mR2(4)$	0.048	G#

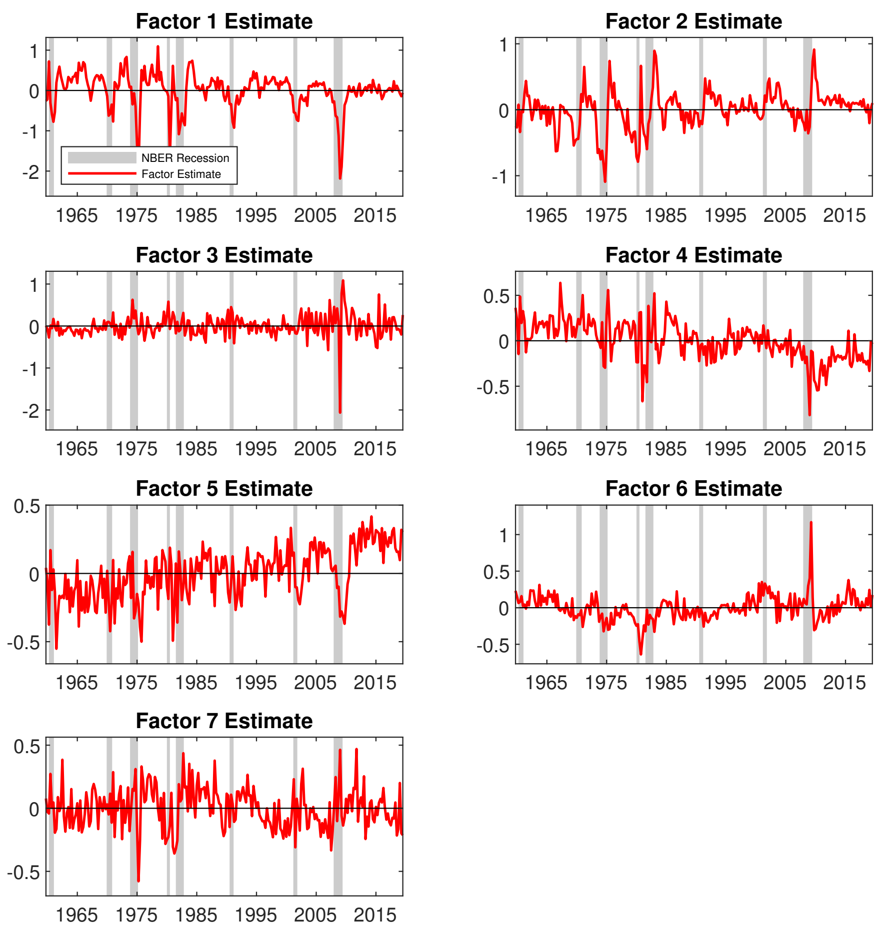
Note: This table lists the 10 series that load most heavily on all four factors along with the R^2 in a regression of the series on the factor. For example, factor 1 of FRED-QD explains 0.784 of the variation in LNS14000025. The first factor of FRED-QD has an mR^2 of 0.211. This is the fraction of the variation in 125 series explained by the first factor. Results for the S&W data set are also listed.

Figure 2: FRED-QD Factor Estimates



Note: This figure plots the PCA-based factors estimated using the full FRED-QD data set based on the benchmark transformation codes.

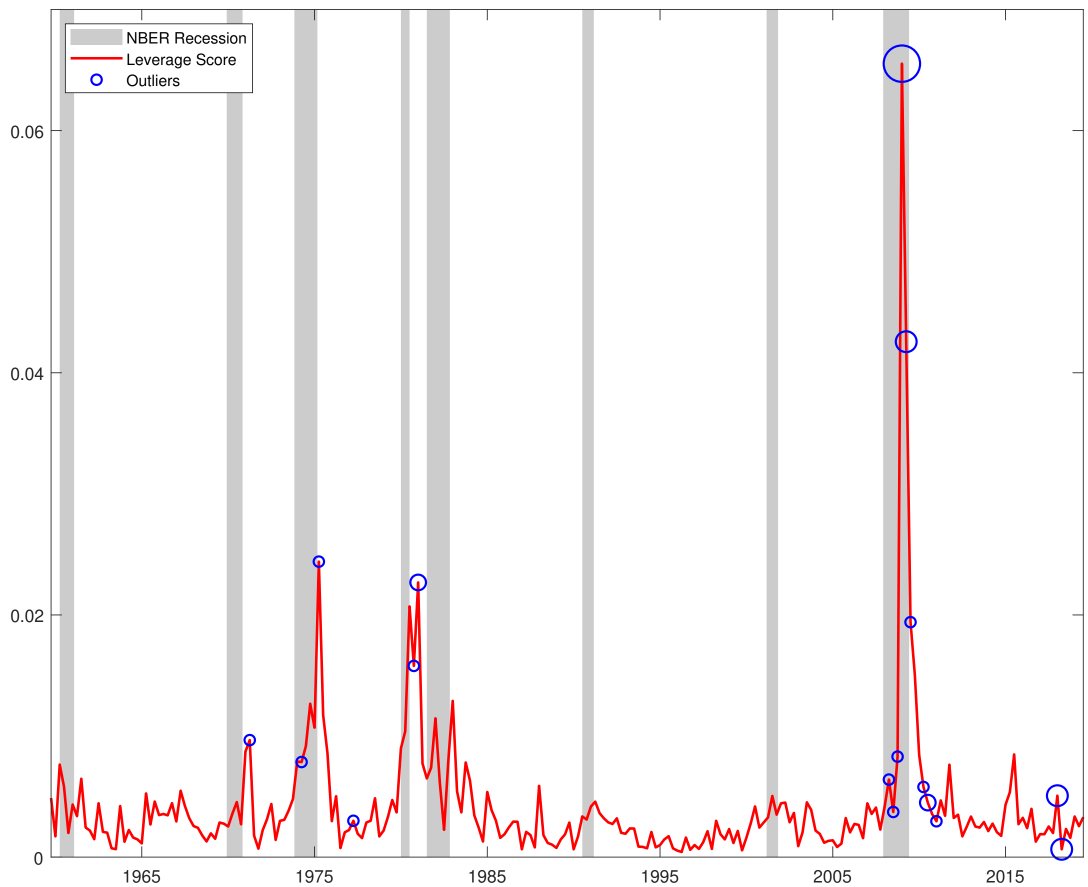
See Table 2 note.

Figure 3: FRED-QD Leverage Scores

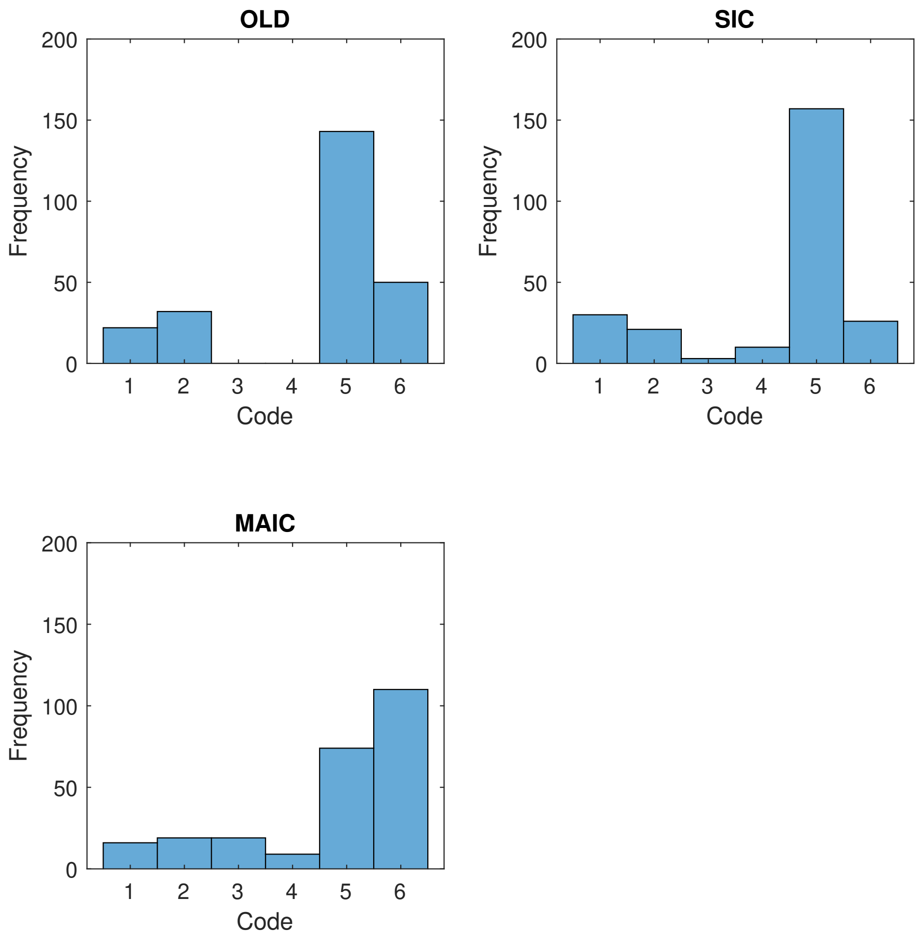


Note: This figure plots the statistical leverage score, p_t, of each quarter. Blue circles represent quarters where at least one series' value was an outlier and are sized relative to how many outliers were detected.

Table 4: FRED-QD Median Transformation Codes by Group

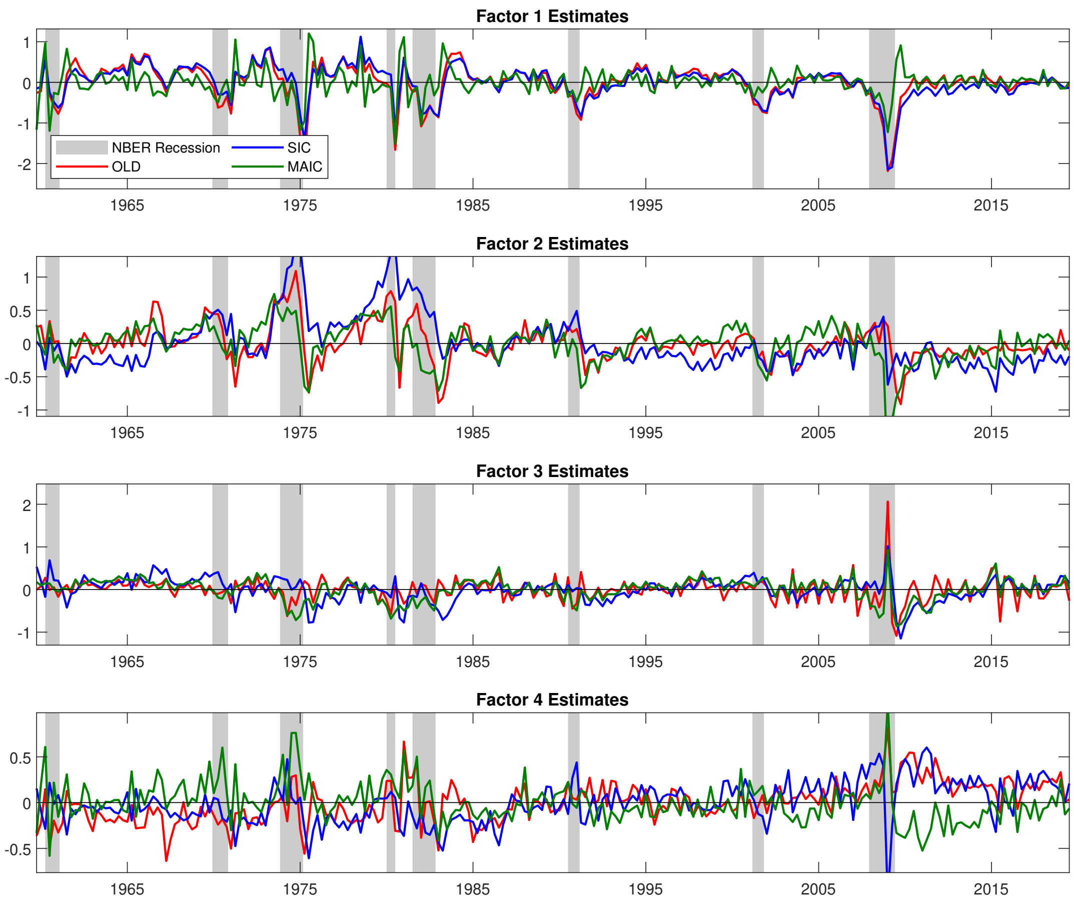
Group	Group Name	OLD	SIC	MAIC
1	NIPA	5	5	6
2	Industrial Production	5	5	6
3	Employment and Unemployment	5	5	5
4	Housing	5	4.5	4.5
5	Inventories, Orders, and Sales	5	5	6
6	Prices	6	5	6
7	Earnings and Productivity	5	5	6
8	Interest Rates	1.5	1	2
9	Money and Credit	5	5	5
10	Household Balance Sheets	5	5	5
11	Exchange Rates	5	5	5
12	Other	1.5	1	1
13	Stock Markets	5	5	5
14	Non-Household Balance Sheets	5	5	5
All		5	5	5

Figure 4: FRED-QD Transformation Code Frequency by Group



Note: Each subpanel provides a histogram of frequencies of transformation codes. "OLD" refers to the benchmark codes provided in FRED-QD. "SIC" and "MAIC" refer to codes implied by the associated DFGLS unit root test.

Figure 5: FRED-QD Factor Estimates by Method of Series Transformation



Note: This figures plots the first four PCA-based factors corresponding to the benchmark (OLD) codes and those implied by the unit root tests (SIC and MAIC).

Notes to Table 6 and 7: This table lists the 10 forecasting models with the lowest RMSE for four series at the 1-quarter and 4-quarter horizons. The combination of factors, use of old or new codes, and ratio of RMSE with the benchmark model (AR(4) w/ old codes) are given. Asterisks denote if the model is significantly better than the baseline at the 5% level using Fixed-b critical values. The # of total/New models in the MCS and the # of Old/New models significantly better than the baseline model are also listed for each dependent variable and horizon.

Appendix

FRED-QD is a quarterly frequency companion to FRED-MD. It is designed to emulate the dataset used in "Disentangling the Channels of the 2007-2009 Recession" by Stock and Watson (2012, NBER WP No. 18094) but also contains several additional series. The columns denote the following: (i) ID denotes the series number, (ii) SW ID denotes the series number in SW (2012), (iii) TCODE denotes one of the following data transformations for a series x: (1) no transformation; (2) Δx_t; (3) $\Delta^2 x_t$; (4) $log(x_t)$; (5) $\Delta \log(x_t)$; (6) $\Delta^2 \log(x_t)$. (7) $\Delta(x_t/x_{t-1} - 1.0)$, (iv) SW FACTORS denotes whether a series was used in SW (2012) when constructing factors (i.e. 1 is yes and 0 is no), (v) FRED MNEMONIC denotes the mnemonic we use for the dataset, (vi) SW MNEMONIC denotes the mnemonic used in SW (2012), and (vii) DESCRIPTION gives a brief definition of the series. The series are loosely grouped based on SW (2012).

Details on construction of the data will be forthcoming, but a few general comments are in order. First, if the FRED mnemonic does not end in "x" then the series comes directly from the FRED database (e.g. PCECC96; real PCE). Otherwise, the series is a modified variant of a series from FRED (e.g. PCDGx; nominal PCE durables is manually deflated using the PCE price index). The exception to this rule is the S&P data, which is taken from public sources. Lastly, monthly frequency series are aggregated to a quarterly frequency using averages.

Group 1: NIPA

	ID	SW ID	TCODE	SW FACTORS	FRED MNEMONIC	SW MNEMONIC	DESCRIPTION
1	1	1	5	0	GDPC1	GDP	Real Gross Domestic Product, 3 Decimal (Billions of Chained 2012 Dollars)
2	2	2	5	0	PCECC96	Consumption	Real Personal Consumption Expenditures (Billions of Chained 2012 Dollars)
3	3	3	5	1	PCDGx	Cons:Dur	Real personal consumption expenditures: Durable goods (Billions of Chained 2012 Dollars), deflated using PCE
4	4	4	5	1	PCESVx	Cons:Svc	Real Personal Consumption Expenditures: Services (Billions of 2012 Dollars), deflated using PCE
5	5	5	5	1	PCNDx	Cons:NonDur	Real Personal Consumption Expenditures: Nondurable Goods (Billions of 2012 Dollars), deflated using PCE
6	6	6	5	0	GPDIC1	Investment	Real Gross Private Domestic Investment, 3 decimal (Billions of Chained 2012 Dollars)
7	7	7	5	0	FPIx	FixedInv	Real private fixed investment (Billions of Chained 2012 Dollars), deflated using PCE
8	8	8	5	1	Y033RC1Q027SBEAx	Inv:Equip&Software	Real Gross Private Domestic Investment: Fixed Investment: Nonresidential: Equipment (Billions of Chained 2012 Dollars), deflated using PCE
9	9	9	5	1	PNFIx	FixInv:NonRes	Real private fixed investment: Nonresidential (Billions of Chained 2012 Dollars), deflated using PCE
10	10	10	5	1	PRFIx	FixedInv:Res	Real private fixed investment: Residential (Billions of Chained 2012 Dollars), deflated using PCE
11	11	11	1	1	A014RE1Q156NBEA	Inv:Inventories	Shares of gross domestic product: Gross private domestic investment: Change in private inventories (Percent)
12	12	12	5	0	GCEC1	Gov.Spending	Real Government Consumption Expenditures & Gross Investment (Billions of Chained 2012 Dollars)
13	13	13	1	1	A823RL1Q225SBEA	Gov:Fed	Real Government Consumption Expenditures and Gross Investment: Federal (Percent Change from Preceding Period)
14	14	14	5	1	FGRECPTx	Real Gov Receipts	Real Federal Government Current Receipts (Billions of Chained 2012 Dollars), deflated using PCE
15	15	15	5	1	SLCEx	Gov:State&Local	Real government state and local consumption expenditures (Billions of Chained 2012 Dollars), deflated using PCE
16	16	16	5	1	EXPGSC1	Exports	Real Exports of Goods & Services, 3 Decimal (Billions of Chained 2012 Dollars)
17	17	17	5	1	IMPGSC1	Imports	Real Imports of Goods & Services, 3 Decimal (Billions of Chained 2012 Dollars)
18	18	18	5	0	DPIC96	Disp-Income	Real Disposable Personal Income (Billions of Chained 2012 Dollars)
19	19	19	5	0	OUTNFB	Ouput:NFB	Nonfarm Business Sector: Real Output (Index 2012=100)
20	20	20	5	0	OUTBS	Output:Bus	Business Sector: Real Output (Index 2012=100)
21	21	21	5	0	OUTMS	Output:Manuf	Manufacturing Sector: Real Output (Index 2012=100)
22	190	n.a.	2	0	B020RE1Q156NBEA		Shares of gross domestic product: Exports of goods and services (Percent)
23	191	n.a.	2	0	B021RE1Q156NBEA		Shares of gross domestic product: Imports of goods and services (Percent)
